Abstract

Internet security incidents have shown that while network cryptography tools like SSL are valuable to Internet service, the hard problem is to protect the server itself from attack. The host security problem is important because attackers know to attack the weakest link, which is vulnerable servers. The problem is hard because securing a server requires securing every piece of software on the server that the attacker can access, which can be a *very* large set of software for a sophisticated server. Sophisticated security architectures that protect against this class of problem exist, but because they are either complex, expensive, or incompatible with existing application software, most Internet server operators have not chosen to use them.

This paper present SubDomain: an OS extension designed to provide sufficient security to prevent vulnerability rot in Internet server platforms, and yet simple enough to minimize the performance, administrative, and implementation costs. SubDomain does this by providing a *least privilege* mechanism for *programs* rather than for *users*. By orienting itself to programs rather than users, SubDomain simplifies the security administrator's task of securing the server.

This paper describes the problem space of securing Internet servers, and presents the SubDomain solution to this problem. We describe the design, implementation, and operation of SubDomain, and provide working examples and performance metrics for services such as HTTP, SMTP, POP, and DNS protected with SubDomain.

1 Introduction

Common server operating systems such as Linux, Windows, Solaris, etc. are subject to *vulnerability rot* as security vulnerabilities (i.e. implementation bugs) are discovered in the component software of these operating systems. For instance, a buffer overflow discovered in the BIND domain name server [15] allowed remote attackers to gain root privileges on a variety of system platforms, and a similar vulnerability in Microsoft's IIS (web server) [21] allows remote attackers to gain administrative control of Windows servers. The recommended defense for general purpose servers is to keep the host system up to date with vendor patches to close these vulnerabilities.

However, many of these systems are being pressed into use as the basis for *server appliances*: servers intended for largely unattended operation by unskilled users. But because these operating systems are subject to vulnerability rot, they need to be frequently upgraded with vendor patches. While this is an acceptable approach for general purpose servers (where a skilled system administrator is expected to maintain the system) it is *not* acceptable to appliance users, who expect a device with the maintenance factor of a toaster.

The classical security solution to vulnerability rot is the notion of *least privilege*: the technique of granting subjects in a system precisely the capabilities they need to perform their function, and no more [33]. Effective use of least privilege *minimizes* the potential damage that results when a trusted program is penetrated by minimizing the degree to which the program is trusted.

Security architectures that provide least privilege mechanisms exist, but because they are either complex, expensive, or incompatible with existing application software, appliance vendors have not chosen to use them. Existing defenses entail these complexities precisely because they were designed to handle the generality of a general purpose server, and thus must deal with *user* least privilege. This generality complicates the least privilege abstraction, making the enforcement mechanism more complex to implement and use.

This paper present SubDomain: an OS extension designed to provide sufficient security to prevent vulnerability rot in server appliances, and yet simplify as much as possible to minimize the performance, administrative, and implementation costs. SubDomain does this by providing a least privilege mechanism for *programs* rather than for *users*. The security restrictions *complement* the system's existing permissions, allowing a *program* to be secured independent of who may be using the program. This notion is especially effective on server appliances, and enables program-specific confinement information to be distributed *with the program* (see Section 4).

By specifically addressing least privilege for programs, we can provide a mechanism that has a relatively small implementation and simple operation. Small implementations are important for security systems to avoid vulnerabilities due to bugs in the enforcement mechanism itself. Simple operation is important for security systems to avoid misconfiguration. Even more so than in most OS design issues, parsimony is critical to security [33] making SubDomain's relative simplicity of design and implementation an important feature.

We present the SubDomain notation for recursively specifying the sub-domain of resources available to a software component, our implementation of SubDomain as an enhancement to the Linux kernel, our application of SubDomain confinement to several example applications, performance metrics on the cost of SubDomain confinement, and our analysis of the security of a system protected by SubDomain.

The challenge of supporting least privilege is to provide a specification system that is expressive enough to specify privileges that are actually minimal, is convenient enough that administrators can reasonably specify least privileges, and yet preserves compatibility and performance. While SubDomain strives for simplicity relative to other least privilege mechanisms, it provides for finer granularity least privilege in one important regard: SubDomain can confine *arbitrary* software components, at a finer granularity than the native OS process, i.e. procedures and modules. This is especially important for component-based services such as Apache [2] and its loadable modules (see Section 3.2).

The rest of this paper is organized as follows. Section 2 elaborates on the problem of vulnerable/ buggy software, and describes the abstract solution of *least privilege* to minimize the potential damage due to attacks against vulnerable software. Readers familiar with least privilege can skip ahead to Section 3, which describes the SubDomain security enhancement, and how it advances over previous least privilege mechanisms by providing finer granularity, and simplifying the problem of confining suspect *programs.* Section 4 demonstrates SubDomain's compatibility by confining assorted software components, including *sub-process* modules. Section 5 presents the performance costs of SubDomain confinement. Section 6 describes related work specifically addressing the problem of confining suspect programs. Section 8 presents our conclusions.

2 The Problem: Vulnerable Programs and Least Privilege

Many security vulnerabilities result from bugs in "trusted" programs. A "trusted program" is a program that runs with privilege that some attacker would like to have, and the program fails to keep that trust if there is a bug in the program that allows the attacker to acquire that privilege. Some examples include:

Buffer Overflows: Many privileged programs contain "buffer overflow" vulnerabilities, a problem endemic to C programs that provide poor bounds checking on user-supplied input. Buffer overflows are very common [6, 7] and very dangerous [21, 20], allowing attackers to take control of programs from an anonymous node on the internet.

Race Conditions: Many privileged programs also contain "race condition" vulnerabilities. Here, the problem is that careless **`root`** privileged processes create files without adequate checking for the prior existence of the file. The problem is that the attacker can create a symbolic or hard link in the file system *between* the time the privileged program checks for existence and the time it creates the file, with the result that the **`root`** program unwittingly uses its authority to corrupt some other critical file [12].

Special Character Processing: While few **`root`** privileged programs are written in shell scripting languages, many other programs with "interesting" privileges are written as shell scripts, especially CGI/PERL [41] programs for processing web forms. CGI programs run with the authority of the web server, and must process arbitrary input from arbitrary users. If the attacker can provide input (using creative URLs) to a CGI program that yields control to the attacker, then the attacker can gain control of the web server, e.g. the PHF program (included in early NCSA and Apache web servers) allowed the attacker to present a URL to the web server that would cause PHF to start an **`xterm`** on the attacker's display [14].

Note that while "trusted" usually refers to highly privileged processes (e.g. **`root`** processes) they can actually be processes with *any* privileges that the attacker wants but does not have. The general

case is that any program installed on a computer that processes input from potentially hostile users becomes a potential vulnerability. Eliminating these vulnerabilities requires some form of assurance that the program in question does not contain exploitable bugs, but this kind of assurance is problematic. Some classes of bugs, e.g. buffer overflow vulnerabilities, can be eliminated through various compiler techniques [39, 5, 26, 37]. Other forms of vulnerabilities are undetectable at compile time, e.g. race conditions [12] and general logic errors.

The only way to assure the complete absence of a security vulnerability in a program is through expensive manual verification. In the absence of such verification, one must either suffer the risk of potential vulnerabilities, or *contain* the potential damage. Note that the activities we seek to constrain are "those that cause damage to the system," i.e. *safety properties* [1] with respect to *integrity*. We are not addressing other security issues, such as *information flows* [27] that might disclose secrets. Readers already familiar with least privilege mechanisms can skip to Section 3 for a description of Subdomain, our contribution to the field.

2.1 The Solution: Least Privilege

The classic solution to the problem of unknown security vulnerabilities is to perform each activity with the *least privilege* required to complete that task [33]. While this does not *stop* exploitation of these vulnerabilities, it does *contain* the damage as much as possible. An attacker who gets control of a least privilege process can, at most, read secrets and corrupt data that the exploited process has access to, and no more.

The challenge of supporting least privilege is to provide a sufficiently *fine-grained* mechanism to specify privileges that are actually minimal, while also preserving compatibility and performance. It is conceptually simple to divide system privileges into fine-grained units and then attribute the exact required privileges to a given activity, but the result of such an approach is specification notation that is tedious to maintain (breaking compatibility) and an enforcement mechanism that is slow (breaking performance).

Practical least privilege therefore involves abstracting the system resources to expedite least privilege specifications. Matching least privilege abstractions to native OS resources in turn enables efficient least privilege enforcement. Least privilege is also a useful notion in managing *user* privileges, leading many systems to combine least privilege for users and programs into a single mechanism, as described in Section 2.1.1.

However, if the problem is bugs in programs that can be accessed by completely untrusted users, then user-oriented least privilege mechanisms may become awkward or inadequately expressive. Section 2.1.2 describes some more elegant approaches to using user privilege mechanisms to confine suspect programs. Section 3 discusses SubDomain, our OS security enhancement that particularly address the problem of least privilege for programs, and Section 6 discusses related work specifically aimed at program confinement.

2.1.1 Using User Privileges to Confine Programs

Least privilege for users is a classic way of structuring a system, and many operating systems provide facilities for constraining the privileges of a given user. User-oriented least privilege facilities can be adapted to confining collection of programs by creating a *synthetic* user, and then running the program as that user.

The classic example is the UNIX setuid facility: the **`setuid`** bit for an executable file indicates that the program runs with the privilege of the owner of the file instead of the privilege of the invoking user. Often this is used to create **`setuid root`** programs that provide controlled access to protected resources by *expanding* the privileges the program runs with to be all of **`root`**'s privileges. To use **`setuid`** to confine a program to a *smaller* set of resources, a new *synthetic* user can be created that has those privileges, e.g. **`nobody`**. Programs can then be made **`setuid nobody`** to confine their actions to a small set of privileges.

One limitation to this approach is that *all* user-IDs, even synthetic user-IDs, can access all files on the system that permit "other" accesses. Another limitation to this approach is that only root can create new user-IDs. The result is that normal users cannot construct *ad hoc* "sandboxes" for programs that they may choose to install and run. Users are then left with their choice of:

- beg the system administrator to create a new user-ID for them,
- do not install software that is not trusted,
- run untrusted software without protection, none of which is very appealing.

So in principle, synthetic user-IDs and the **`setuid`** mechanism can support least privilege for programs, but in practice it forces **`root`** to do all the work. Therefore this technique is rarely deployed, people run un-trustworthy software with much more privilege than is necessary, and suffer the consequent security risks.

2.1.2 Users and Roles

Because synthesizing user-IDs is awkward, the notion of a *role* emerged. A role is a collection of related privileges [2]. In 1986, Bobert and Kain introduced the notion of *type enforcement*: objects (files) are assigned to *types*, subjects (processes) are assigned to *domains*, and tables determine which domains have access to which types. Badger et al expanded on this notion [7, 8]. In a similar vein, *role-based access control (RBAC)* [22, 34] assigns users to roles, and then grants privileges to the roles.

Similar to the **`setuid`** approach described in Section 2.1.1, roles can be pressed into service confining programs to a least privilege set of resources by assuming a specific role just prior to executing the program. While using roles to confine programs is more elegant than synthesizing user-IDs, it is still fundamentally overloading a user-oriented access control mechanism to manage software defects. In Section 3, we describe our mechanism to specifically address the problem of vulnerable software.

3 SubDomain Security: Recursive Component Confinement

SubDomain is a kernel extension designed specifically to provide least privilege confinement to suspect programs. SubDomain allows the administrator to specify the *domain* of activities the program can perform by listing the files the program may access, and the operations the program may perform. SubDomain restrictions *complement* the native access controls, in that SubDomain never *expands* the set of files a program may access, i.e. any file access must pass the native access controls and the SubDomain restrictions before access is granted. Thus SubDomain confinement makes a program monotonically safer to run.

```
foo {
/etc/readme       r ,
/etc/writeme      w ,
/usr/bin/bar      x ,
/mydir/*          r ,
}
```

Figure 1 Trivial SubDomain

Section 3.1 describes the SubDomain notation and semantics. Section 3.2 explains how SubDomain leverages work in safe programming models like *proof-carrying code* [30] to achieve component confinement *below* the granularity of a native process. Section 3.3 describes the SubDomain implementation.

3.1 SubDomain Notation & Semantics

Figure 1 shows a trivial SubDomain specification, in which the **`foo`** program is given read access to the **`/etc/readme`** file, write access to the **`/etc/writeme`** file, and execute access to the **`/usr/bin/bar`** file. When ever the program **`foo`** is run, by any user, it is restricted to access these specified files with these modes. SubDomain profiles can also grant access to directories through simple globbing, i.e. the profile in Figure 1 grants the **`foo`** program to all files in **`/mydir`**.

The **`x`** (execute) capability is of particular importance: what restrictions should apply to the child process? By default, the child process inherits the parent's SubDomain, preventing the confined program from "escaping" its confinement by executing an unrestricted child process. However, sub-components of an application may require different capability sets than the application as a whole. For instance, games only need strong privileges to initialize video controllers, and mail delivery agents only need strong privileges to actually write to a user's mail box. Thus child programs can be given different constraints by specifying a *relative subdomain*, denoted by a **`x`** followed by a + or - followed by a SubDomain specification. For example, Figure 2 shows a SubDomain for **`foo`** that says that when the sub-component **`bar`** is run, it can *also* have write permission to the **`/etc/otherwrite`** file. Conversely, it says that when **`foo`** runs the sub-component **`baz`**, it may *not* write to the **`/etc/writeme`** file.

Sub-components may also want a SubDomain that is completely unrelated to the parent domain. For example, a web server application might need to send some e-mail while processing a web form, and thus invokes a mail delivery agent whose SubDomain is completely different. We support this need with *absolute subdomains*, denoted by a subdomain specification following an **`x`** *without* a + or a -. Figure 3 shows an example absolute subdomain in which the `bar` program run from the **`foo`** program has access to a completely different subdomain than the **`foo`** program.

When a confined process tries to perform a file operation that is not permitted, two things happen:

```
foo {
/etc/readme       r ,
/etc/writeme      w ,
/usr/bin/bar      x     +{/etc/otherwrite       w} ,
/usr/bin/baz      x     -{/etc/writeme          w} ,
}
```

Figure 2 Relative SubDomain

1. The syscall returns with the error EPERM, just as if the attempt had failed due to a standard UNIX file system permission error.
2. The kernel generates a syslog entry describing the attempted violation. Intrusion detection systems can thus collect what ever information they want, and act accordingly.

3.2 Sub-process Confinement

Section 6 describes several other systems that provide program-confinement mechanisms. However, with the exception of Java [4] the smallest component that they can confine is a native OS process. In contrast, SubDomain provides the unique feature of being able to confine components that are only a *portion* of an OS process. Historically of little practical interest, the need for sub-process confinement comes from the rise in popularity of scriptable servers and loadable modules. Let us expand upon these concepts.

A "scriptable server" is a server program that, from time to time, interprets a script or a program within itself, i.e. *server-side includes* [5], PHP web pages [6], Java *servlets* [3], etc. Such scripts are legitimately sub-component programs requiring separate confinement. Scriptable servers often have their own security mechanisms, but in depending on such restrictions, we are depending on application correctness, which is the dependence we seek to avoid in the first place. We would rather have a confinement mechanism that can be enforced by the operating system so that we do not depend on the correctness of the server application.

"Loadable modules" or "plug-ins" is the notion of providing a (fairly) fixed API in an application so that extensions to can be loaded into the application, either at start-time or run-time. "Plug-in" is the common term for desktop applications (i.e. Netscape Navigator & Shockwave, Microsoft Word and EndNote) while "module" is the common term for servers (e.g. Apache and mod_perl).

The **`mod_perl`** module for Apache provides a perfect example of the sub-process problem. PERL scripts run at the behest of the Apache web server are normally interpreted by starting a separate process to run the PERL interpreter, and then interpreting the PERL script in that separate process. **`mod_perl`** loads a PERL interpreter directly into the Apache process to avoid the cost of starting the PERL interpreter process. While this is good for server throughput, it is bad for security:

- Bugs in **`mod_perl`** can crash the Apache web server process.
- Program-confinement mechanisms that only operate on OS processes cannot confine scripts interpreted by **`mod_perl`** separate from the Apache web server process.

The SubDomain solution to the "scripting & module" problem is to provide for subdomains for sub-process components, in cooperation with the enclosing application. The notation for a sub-process subdomain is unchanged from that of separate-process subdomains shown in Figure 1 through

```
foo {
/etc/readme       r ,
/etc/writeme      w ,
/usr/bin/bar      x     {
      /usr/lib/otherread      r ,
      /var/opt/otherwrite     w ,
      } ,
}
```

Figure 3 Absolute SubDomain

Figure 3. The effect is to create a variety of "hats" that process can wear, one for each sub-process component that it calls. The "cooperation" required from the enclosing program is that it should call the new **`change_hat()`** system call before calling the sub-process component.

The requirement to call **`change_hat()`** implies that we are once again trusting the application, which SubDomain is supposed to avoid. However, we are trusting the application code a great deal *less*, in that the application only has to make appropriate calls to **`change_hat()`**, which is much simpler than constructing and enforcing an effective "sandbox" environment [9]. Successfully calling **`change_hat()`** with the name of a sub-component before calling the sub-component seems easy enough to do correctly.

In addition to the requirement that enclosing application correctly calls **`change_hat()`**, we also require that the sub-component does *not* call **`change_hat()`** to escape to a more liberal subdomain. Here, we employ a *cookie* argument to change_hat() to prevent the confined module from escaping. The containing process initially calls **`change_hat()`** with a particular cookie value, and further **`change_hat()`** calls that do not provide a matching cookie argument are treated as security violations.

Thus for the containing process to prevent sub-component from escaping from the **`change_hat()`** SubDomain, it need only provide a cookie value that the contained sub-component cannot easily guess. We recommend fetching a word from **`/dev/random`**, but any reasonable source of entropy can be used.

The security of this method depends on the sub-component *not* being able to read the parent process's cookie value. Here, SubDomain can leverage the power of *language*-based security protection systems such as proof-carrying code [30], strong type checking [39, 26, 37], and other language-based protection schemes [24, 40]. Such methods can, in principle, *prove* that the sub-component will not invoke the **`change_hat()`** system call.

Programing language techniques provide powerful protection, but also impose significant practical constraints, not the least of which is that the sub-component needs to be written in a particular language. In practice, we can still get reasonable assurance that the sub-component cannot read the containing process's cookie value if it is written in a scripting language, i.e. a language that is *interpreted* rather than one compiling to native CPU instructions. In the practical setting of scripts for web servers, most such programs that are executed by loadable modules are scripting languages, e.g. PERL [41], PHP [6], and Java [3]. While no *formal* assurances are available, in practice it is easy to trust, say, **`mod_perl`** to not address random memory.

To see the power of this approach, consider the chronic problem of securely supporting Microsoft's "Front Page Extensions," a collection of non-standard HTML tags that the server interprets to provide more dynamic HTML content. Microsoft provides a **`mod_fp`** Apache module and collection of helper programs, but they have a poor security history [36]. There is no current practical method to securely support **`mod_fp`**.

SubDomain can solve the **`mod_fp`** problem by treating web pages containing "Front Page Extensions" tags as sub-components, and assigning each such page to a subdomain. So long as the **`mod_fp`** module can be trusted not to call the **`change_hat()`** system call, then no errant action of **`mod_fp`** can violate the security policy of the subdomain for the page it is interpreting.

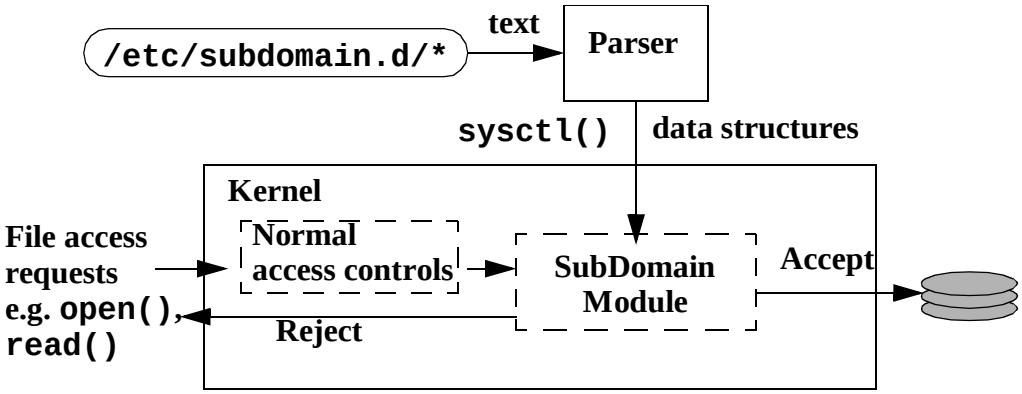

Figure 4 SubDomain Implementation

3.3 SubDomain Implementation

The basic architecture of SubDomain is shown in Figure 4. The SubDomain policy engine is implemented as a Linux [27] loadable kernel module. Following the usual UNIX permissions checking, the relevant system calls (**`open()`**, **`exec()`**, **`read()`**, etc.) are modified to check if the calling process is a confined process. If so, the request is referred to the SubDomain module for further inspection. The SubDomain module then either returns normally (if the request is permitted) or returns an EPERM error (if the request is denied).

Once loaded, the SubDomain module disables module unloading to prevent tampering with the SubDomain policy engine. A user-level parser reads subdomain profiles from **`/etc/subdomain.d/*`** to convert the textual representation of profiles into kernel data structures, and inserts the updated profiles into the kernel via a **`sysctl()`** interface. By convention, the **`/etc/subdomain.d/foo`** file would confine the **`foo`** program, but as shown in Section 3.1, the actual name of the confined program is in the file, so confining multiple components with a single file is possible. Only root processes can access this kernel interface, and SubDomain-confined programs may *not* access the profile interface. In future work we will add further authentication requirements to the kernel's profile interface.

3.4 SubDomain Parsimony

SubDomain is simpler than competing least privilege mechanisms described in Section 6 in both implementation and usage. With regard to implementation, the SubDomain module and kernel patches amount to 4500 lines of C code, and the non-kernel parser is 825 lines. In contrast, the DTE kernel enhancement [7, 8] is over 40,000 lines of code. The relatively simple semantics of SubDomain enable a smaller implementation. "Smaller" is important for security systems, where correctness is critical, because bugs are approximately liner in code size.

SubDomain's usage is simpler than its competitors in that it is easier to devise and inspect SubDomain confinement profile than in other systems, which we elaborate on in Section 4.

4 SubDomain Compatibility

We test the compatibility of SubDomain by putting it to work confining a variety of software components common to Internet servers, both large and small. SubDomain can confine binary-only

programs, so long as there is no need for sub-process confinement. If sub-process confinement is required, then the program source needs to be edited and re-compiled to insert appropriate calls to **`change_hat()`** (see Section 3.3).

Like the "synthetic user" approach in Section 2.1.1, SubDomain confinement requires administrator intervention. However, SubDomain confinement is easier for the administrator in the following ways:

Ease of Application: A SubDomain profile does not interfere with any other aspects of the system except the SubDomain mechanism. Thus it is easy to install a Subdomain profile along with the confined program. In particular, because the SubDomain profile is independent of the system the program is being installed on, the profile can be *included* with the program being distributed. In contrast, it is difficult to include a synthetic user in conventional program packages (e.g. tar balls or RPM packages). [1]

Ease of Inspection: It is easy for the administrator to inspect a SubDomain specification to determine the precise aspects of the system that are exposed to that program. In contrast, the exposure entailed by a synthetic user is non-obvious: the administrator must consider all files that are accessible to "anybody," which is a non-trivial exercise on non-trivial file systems.

The Kernel Wrapper approach [23] (see Section 6.5) provides for confinement scripts that are full Turing-equivalent programs. While this provides extensive flexibility, it also means that the completeness and safety of an inserted kernel wrapper is not amenable to automatic analysis. In contrast, SubDomain profiles are easy to inspect to determine the security implications of updating a SubDomain profile. Furthermore, it is *strictly* safe to install a SubDomain profile where none existed before, because SubDomain strictly limits program privileges.

These factors have important implications for software distribution. Because SubDomain confinement profiles are system independent and guaranteed to be safe to install, it becomes feasible to package SubDomain confinement *with the program itself*. Thus an end user can consider installing a new program on a server appliance, and because of the SubDomain confinement information packaged with the program, the user can understand the security implications of installing that program. In future work, we plan to develop future tools that will assist the administrator in determining the security implications of a set of SubDomain confinements

Which programs need to be confined with SubDomain depends on the convenience and security needs of the host system, and thus is an adjustable policy. The administrator can specify which of the following classes of programs must be confined with SubDomain before they are allowed to execute at all:

All Programs: All programs that execute on the host must be associated with a SubDomain, either explicitly, or inherited from a SubDomained parent program. This mode is suitable for bastion hosts.

All Listed User-IDs: All programs running under one of the user-IDs specified by the administrator must be associated with a SubDomain. For instance, the httpd user-ID runs many programs on behalf of the web server, and SubDomain confinement ensures that these programs will not

1.Note that bundling synthetic user IDs is exactly the approach taken by **`qmail`** [11], which results in excellent security for **`qmail`**, but also imposes substantial packaging difficulties that have hampered **`qmail`**'s spread.

affect other parts of the system. This mode is suitable for confining a potentially vulnerable collection of services on a system that also hosts critical data.

All `root` Programs: All programs running with a real or effective user-ID of "`root`." This mode allows a SubDomain profile to be used to achieve the classic goal of breaking up root's all-too-powerful privileges. The (defunct) POSIX 1.e "capabilities" model subdivided root's powers into a static set of 32 separate groups of "capabilities", and individual programs could assume *part* of root's powers by flipping on one or more of these sets of capabilities. SubDomain allows arbitrary sets of privileges to be grouped together, rather than accepting the groupings specified by POSIX 1.e.

Only Specified Programs: Only the programs that have a SubDomain specified are thus confined, i.e. "default allow." This mode assumes that all programs on the host are adequately secured *except* for the programs being SubDomained. While not especially secure, this mode is convenient, e.g. for use on a client workstation to run a suspect program recently downloaded from the Internet.

The procedure for confining a program is to start with a null subdomain specification, run the application, observe the system log for complaints about attempts to access files outside the subdomain, and then add those files to the subdomain specification. This procedure is presently manual, because due consideration is required for two stages in this procedure:

Running the application: The application needs to be run under all of the "kinds" of input that it is expected to experience in a production environment, i.e. a comprehensive test suite. Determining these inputs requires some knowledge of the application to ensure complete coverage. Failure to provide complete coverage results in a subdomain that is too "tight", and the application will occasionally fail to access resources that it needs.

Granting the privilege: We are confining the application precisely because we do *not* trust it, and therefore we cannot automatically assume that every file the application tries to access under test is a legitimate file for the program to access. The file should be included in the subdomain only after due consideration of the security implications.

For applications where source code is available, predicting the set of required resources should be feasible. If anticipating the set of files an application needs to access is truly difficult, then it is quite likely that the application represents a significant security threat, and should not be installed on hosts requiring security.

For applications where source code is not available, a run-time testing methodology must be used to experimentally identify all of the file resources that a program may try to access. To facilitate this, we use the **`dep`** program that we developed for the InDependence project [16] (funded by a student grant from USENIX). This program uses **`strace()`** to monitor the execution of a subject program, and amasses a list of all the files accessed. **`dep`**'s use of **`strace()`** imposes heavier performance and compatibility overhead than SubDomain, but is none the less sufficient for exploring the file system domain of many programs. To further ease use, **`dep`** accumulates files accessed across multiple runs, so that a large test suite can be applied, and then the list of files accessed inspected once at the end of testing.

An example subdomain profile is shown in Figure 5, providing all of the resources needed to run the wwwcount CGI program (a popular web page hit counter program). Note the use of simple

```
/home/httpd/cgi-bin/Count.cgi   {
/etc/ld.so.cache                          r ,
/lib/lib*                                 r ,
/lib/ld-linux.so.2                        r ,
/etc/nsswitch.conf                        r ,
/etc/wwwcounter.conf                      r ,
/etc/localtime                            r ,
/var/log/httpd/wwwcount/wwwcount_log      rw ,
/var/lib/wwwcount/*                       r ,
/var/lib/wwwcount/data/*                  rw ,
}
```

Figure 5 Subdomain for `wwwcount` CGI script

globbing to reduce the size of the subdomain specification when access to an entire directory is required. Figure 6 shows a more elaborate profile for the Apache web server itself, under a particular configuration. A list of some of the programs that we have confined and tested, along with the size of their subdomains, are listed in Table 1.

5 SubDomain Performance

Here we present a variety of SubDomain performance measurements. Section 5.1 describes our microbenchmarks on mediated system calls, and Section 5.2 describes our macrobenchmarks on a confined PERL script interpreted by the **`mod_perl`** Apache module.

```
/usr/local/apache/bin/httpd {
/                                         r  ,
/dev/null                                 rw ,
/dev/urandom                              r  ,
/etc/group                                r  ,
/etc/hosts                                r  ,
/etc/host.conf                            r  ,
/etc/ld.so.cache                          r  ,
/etc/localtime                            r  ,
/etc/nsswitch.conf                        r  ,
/etc/passwd                               r  ,
/etc/resolv.conf                          r  ,
/home/httpd/perl/*                        r  ,
/lib/*                                    r  ,
/usr                                      r  ,
/usr/lib/gconv/ISO8859-1.so               r  ,
/usr/lib/gconv/gconv-modules              r  ,
/usr/lib/perl5/5.00503/*                  r  ,
/usr/lib/perl5/site_perl/5.005/i386-linux/* r  ,
/usr/local                                r  ,
/usr/local/apache                         r  ,
/usr/local/apache/conf/*                  r  ,
/usr/local/apache/htdocs/*                r  ,
/usr/local/apache/logs*                   wl ,
/usr/share/locale/en_US/*                 r  ,
/usr/share/locale/locale.alias            r  ,
}
```

Figure 6 Subdomain for `Apache` Web Server

Table 1: SubDomain-confined Programs

Program	Size of Subdomain
Simple **bash** shell script	31 files
PHF CGI program	14 files
CGI Mail program	7 files
htsearch CGI program	11 files
wwwcount CGI program	10 files
Apache web server	33 files
lpd	16 files
lpq	10 files
lpc	11 files
Postfix Mail Delivery Agent	15 files
Postfix-script helper program	65 files

5.1 Microbenchmarks

Here we use the usual benchmarking technique to measure affected system calls by crafting programs that issue each system call 10,000 times, run the programs several times, discard the first run to avoid cold cache effects, and average the remainder. All tests were performed on a dual-processor Pentium III 700 MHz, with 256 MB of RAM. Table 2 summarizes these results. We include measurement of the **get_pid()** system call as a baseline for comparison against the **change_hat()** system call, as **get_pid()** is commonly regarded as the simplest system call.

Table 2: SubDomain Microbenchmarks in microseconds

System Call	Standard Cost	SubDomain Cost	% Overhead
fork()	295	295	0%
exec()	1387	1487	7%
open()	3.71	5.39	45%
get_pid() vs. **change_hat()**	1.81	4.70	159%

As expected, he major overhead appears in the **open()**, **exec()** and **change_hat()** system calls, where SubDomain is checking the action against the subdomain specification for the confined process.

5.2 Macrobenchmarks

Our macrobenchmark is SubDomain confinement of a PERL script to be executed via the mod_perl Apache module, thus exercising SubDomain's capability to confine *active content* scripts. To exercise the web server's cache, we replicated the PERL script 1000 times, and used the Webstone performance benchmark to measure the overhead cost of PERL scripted web pages protected with SubDomain vs. without protection. The PERL script itself reads two files with some busy-work in between, simulating a script that fetches a "container" template from one file, HTML

content from another file, and does some interim processing to merge the two, e.g. compute a hit counter. The SubDomain profile for this script is shown in Figure 7.

The test environment used the same dual-processor Pentium III 700 MHz server with 256 MB of RAM, and a private network (crossover cable) via 100 Mbit ethernet.

The test results are shown in Table 3, measured for 5 to 10 concurrent client connections. Tests were run twice, and the results averaged. For all cases, the SubDomain overhead is between 1% and 2%, i.e. in the noise range.

Table 3: SubDomain Macrobenchmarks with WebStone

Test	# of Clients	Connection Rate	Avg. Response Time (ms)	Avg. Client Throughput
Std.	5	75.97	66.5	26.29
SubDomain	5	75.19	66.5	26.02
% Overhead		1%	0%	1%
Std.	6	78.14	77	27.04
SubDomain	6	76.56	78	26.49
% Overhead		2%	1.3%	2%
Std.	7	78.38	89	27.13
SubDomain	7	77.24	90.5	26.73
% Overhead		1.45%	1.7%	1.5%
Std.	8	78.26	102	27.08
SubDomain	8	76.71	104	26.54
% Overhead		2%	2%	2%
Std.	9	78.24	115	27.08
SubDomain	9	77.02	116.5	26.66
% Overhead		1.6%	1.3%	1.6%
Std.	10	78.43	127	27.15
SubDomain	10	77.07	129.5	26.67
% Overhead		1.7%	2%	1.7%

```
/perl/0/cgitest-001.cgi {
/usr/lib/perl5/site_perl/5.005/i386-linux/Apache/Registry.pm    r
/etc/localtime                                                  r
/usr/lib/perl5/5.00503/*                                        r
/home/httpd/perl/0/cgitest-001.cgi                              r
/home/httpd/perl/0/cgitemplate-001.html                         r
/home/httpd/perl/0/cgidata-001                                  r
/var/log/httpd/*                                                w
}
```

Figure 7 Test PERL Script's SubDomain Profile

6 Related Work

Here we describe work that, similar to SubDomain, specifically attacks the problem of confining suspect programs. Despite the age of the notion of least privilege [33], much of this work has emerged relatively recently. It is our conjecture that this is a result of a shift in emphasis from defending *secrecy* (the dominant concern for military organizations) to defending *integrity* (the dominant concern for Internet-connected businesses) and the emergence of the notion of *survivability* [35]. This list of related work is necessarily partial, as the total body of related work is very large.

6.1 TRON

The TRON system [10] is a kernel enhancement for ULTRIX that can confine a program's execution to a protection domain consisting of a finite set of *capabilities* in the form of file names. TRON adds the **`tron_fork()`** system call, which functions exactly like the classic **`fork()`** system call, except that it specifies the protection domain as an extra argument. TRON is semantically most similar to SubDomain: the protection domains are the same (sets of files) and are similarly applied to host programs, orthogonal to user privileges. The major differences are:

- TRON is discretionary, while SubDomain is mandatory. TRON provides user commands to run programs in a confined domain, while SubDomain always runs a specified program in a confined domain. Thus in the usual DAC vs. MAC trade-off, TRON is more convenient for individual users, while SubDomain is more convenient for securing entire systems, e.g. server appliances.
- TRON's finest granularity is the ULTRIX process; it cannot confine loadable modules (see Section 3.2).

6.2 Janus

Janus [25] is a user-level mechanism for confining programs to a specific set of resources. Intended to confine "helper" applications run from within a Web browser, Janus uses the **`ptrace()`** system call and a monitoring process to mediate all system calls made by the helper application. If the action proposed by the helper application violates a policy set by the user, then the monitoring process rejects the request. This approach requires four system calls to be executed to effect one confined system call.

6.3 Java 2 Security

The Java 2 security model [4] allows the JVM to be configured to assign particular capabilities to designated Java *classes*, similar to the SubDomain notion of assigning file system capabilities to programs. This is an enrichment over the original Java security model [26] which assigned one fixed set of capabilities to remotely-loaded applets (almost nothing), and another fixed set of capabilities to locally-loaded applets (almost everything).

The Java 2 security mechanism is notable as the only system other than SubDomain capable of confining sub-process components, in that Java classes are typically smaller than the host OS processes. Naturally, the Java 2 security model does not apply to non-Java native executables.

6.4 `chroot` Jail

The **`chroot()`** system call[2] makes the argument directory be the effective root directory, i.e. "/" for the invoking process. The point of this operation is that the file system domain for the affected process is now limited to the contents of the argument directory. Any files that the application needs to access must be placed inside the `chroot` directory, or the access will fail.

The **`chroot`** technique is a popular form of confinement, in large part because standard kernels (e.g. Linux) support it. However, **`chroot`** has defects in all three of the dimensions a security enhancement should address:

Security: **`chroot`** jails are resistant to *oblivious* attempts to escape the jail, i.e. attempts to access files that are not accessible within the jail. However, if the attacker can execute their own code within the `chroot` jail, it is fairly easy to break the jail and access outside files. Thus jailed programs generally cannot be trusted with strong privileges, i.e. it is insecure to depend on **`chroot`** to confine a **`root`** process.

Compatibility: Each **`chroot`**'d program must have the necessary components of the file system replicated within its jail, which is problematic if the program requires access to a large, complex set of files, i.e. shell scripts need all invoked programs replicated into the **`chroot`** jail. Thus setting up a **`chroot`** jail can be a lot of tedious, complex work. The **`chroot`** technique also breaks programs that need to interact with other parts of the system.

Performance: Because **`chroot`** jails require duplication of all resources needed by the jailed program (soft or hard links could be used as escape routes) they consume excessive disk space and file system buffer cache space.

6.5 Type Enforcement

The type enforcement work [13, 7, 8] has recently been extended to provide better support for program confinement. *Kernel hypervisors* [28] provide a facility for installing small state machines that intercept kernel system calls and enforce a security policy. Such a facility can be viewed as a tool that could be used to build a SubDomain-like least privilege system. Fraiser, Badger and Feldman provide a similar tool for building security policy enforcement automata [23]. SubDomain provides the following key advantages over this technique:

Parsimony: SubDomain is much simpler than the TE and DTE implementations; the SubDomain kernel code is approximately 1/10 the size of the DTE kernel patch. Simplicity is critical in security systems.

Safety: The DTE Wrapper system [23] allows code to be inserted into the operating system to perform mediation. While this is a powerful technique, it is also dangerous: *malicious* DTE wrapper code could just as easily be inserted. In contrast, SubDomain profiles are easy to inspect to determine the security implications of updating a SubDomain profile. Furthermore, it is *strictly* safe to install a SubDomain profile where none existed before, because SubDomain strictly limits program privileges.[3]

2."`man chroot`" on most UNIX Systems

3.This observation due to Blaine Burnham.

6.6 Application-Specific Mechanisms

Various application environments provide their own least privilege-like mechanisms. For instance, the PERL interpreter includes a facility known as "taint", in which input provided to the PERL script *cannot* be used to formulate an action (i.e. `system()` operation) unless it has been "adequately" inspected by the PERL script [41]. PERL also includes a "safe PERL" facility, where in the programmer can specify a set of PERL operators that the script may not use.

Another application-specific least privilege mechanism is the notion of "wrappers." For example, CGI Wrappers [31] causes a CGI script to be run with the user-ID of the script owner, rather than the user-ID of the web server. Combined with the synthetic user-ID notion described in Section 2.1.1, CGI Wrappers can construct a least privilege environment for CGI scripts.

6.7 PACLs: Program-based Access Control Lists

We believe PACLs [42] to be the first instance of an access control system based on the program performing the operation. The PACL system is the exact dual of the SubDomain notion: files have an access control list that enumerates programs that are permitted to operate on that file. A simulated PACL system was built and evaluated, but an actual PACL system was never finished.

7 Status & Availability

The implementation is not complete with respect to the description in this paper.

- The absolute and relative sub-domains described in Section 3.1is not complete: child processes either inherit the parent's profile, or use their own profile if one is specified.
- The multiple modes of requiring SubDomain confinement described in Section 4 is only partially implemented. The implementation currently supports "paranoid" mode where all processes must have SubDomain confinement, and "open" mode, where only the programs that are specified are confined by SubDomain.

SubDomain is implemented for Linux, and is available from `http://immunix.org` . The kernel enhancement portion is licensed under the GPL, and the non-kernel portions are proprietary to WireX but available for free for non-commercial use.

8 Conclusions

Vulnerable software is a major security problem, mandating constant system administrator attention to keep systems up to date with vendor-supplied security patches. This is especially problematic for complex Internet servers, which are required to provide extensive services to anyone on the Internet. Some form of confinement mechanism to approximate least privilege is the generic solution, but often imposes more costs than administrators deploying in "internet time" can bear. Our SubDomain confinement mechanism advances over previous confinement work, simplifying both implementation and administration overheads by confining *programs* instead of *users*.

This approach enables SubDomain confinement to be packaged with programs, in contrast with confinement mechanisms that are bound to the system. SubDomain also provides fine-grained protection, confining software components *finer* than the host OS process, providing the unique capability to protect potentially vulnerable server *modules* such as Microsoft's Front Page Extensions

to the Apache web server. We have implemented and tested the system, showing that it provides all three essential properties of a security enhancement: enhanced security, software compatibility, and preserved performance.
